Final Technical Report
December 1996

IMPACT OF CHANNEL PROPAGATION ON IMAGE COMPRESSION (ICPIC) A GRAPHICAL SIMULATION TOOL

The Analytic Sciences Corporation

Charles Drutman and John Delmedico

APPROVED FOR PUBLIC RELEASE; DISTRIBUTION UNLIMITED.

19970305 044

[DTIC QUALITY INSPECTED 3]

**Rome Laboratory
Air Force Materiel Command
Rome, New York**

This report has been reviewed by the Rome Laboratory Public Affairs Office (PA) and is releasable to the National Technical Information Service (NTIS). At NTIS it will be releasable to the general public, including foreign nations.

RL-TR-96-199 has been reviewed and is approved for publication.

APPROVED:

RICHARD N. SMITH
Project Engineer

FOR THE COMMANDER:

JOHN A. GRANIERO
Chief Scientist
Command, Control, & Communications Directorate

If your address has changed or if you wish to be removed from the Rome Laboratory mailing list, or if the addressee is no longer employed by your organization, please notify RL/C3BA, 525 Brooks Road, Rome, NY 13441-4505. This will assist us in maintaining a current mailing list.

Do not return copies of this report unless contractual obligations or notices on a specific document require that it be returned.

1.0 Introduction

The ICPIC workstation is an extensible simulation testbed, with a graphical, menu-driven interface, that facilitates plug and play evaluation and design of optimal image compression and communication system configurations. The ICPIC testbed can be used to simulate the entire communication process from original image retrieval, through image compression, error coding, transmission, propagation over a channel, error detection and correction techniques (EDAC), image decompression, and final image display and evaluation.

In addition, image compression algorithms can be evaluated with respect to their performance when used for image transmission over a variety of communication channels. The results of these evaluations can then be used to suggest algorithm modifications which will improve performance over a communication channel.

The ICPIC testbed is modular in design and is built on the Signal Processing Worksystem (SPW) software developed by the Alta Group of Cadence Design Systems, Inc. and the Spread Spectrum Vulnerability Metric (SSVM) software developed by TASC. Use of the ICPIC testbed requires familiarity only with the material covered in the SPW tutorial manual. ICPIC expands the SPW analysis capabilities by providing the user with one standardized graphical interface with which to gain parallel access to all of the capabilities of both the SPW and SSVM module libraries.

ICPIC facilitates the construction of a complete simulation from analysis "primitives" by drag and drop operations. These primitives range in capability from low-level modules such as signal sources and simple scalar multipliers, to high-level modules that perform such capabilities as PSK (Phase Shift Keying) and EDAC (Error Detection and Correction). By utilizing the graphical interface along with the SPW and SSVM module libraries, ICPIC gives the user the capability to quickly construct an end-to-end simulation, allowing for rapid system design assessment and optimization.

The remainder of this section describes the image compression, EDAC, and channel propagation models available in ICPIC as well as the relationship between these components. Section 2 provides a detailed discussion of a complete end-to-end BPSK simulation, including both the image analysis and data preparation software tools which were developed for this effort and are available as part of the ICPIC testbed. Section 3 presents sample data outputs from the BPSK system. Section 4 presents a summary and recommendations for future analysis.

DTIC QUALITY INSPECTED 3

1.1 Image Compression

Image compression algorithms reduce storage and bandwidth requirements by reducing information redundancy in the transmitted image. The smaller the image, the less time the propagation channel has to degrade it by the addition of noise. Individual image compression algorithms are grouped under the higher level classifications of either Lossless or Lossy compression algorithms. Lossless means that the image data can be compressed and decompressed infinitely many times without suffering any loss in the information content. With lossy compression algorithms, there is some information loss every time the image is compressed and decompressed. The amount of loss depends on the compression factor, which is an arbitrary user-defined integer. Depending on the application, it may be acceptable to lose some information if it significantly decreases the transmission time while maintaining sufficient information content.

Depending on the specific image compression technique, certain portions of an image may be more sensitive to errors than other portions. The EDAC techniques can therefore be optimized for the more sensitive portions of the transmitted image. In general, errors in the image header need to be eliminated or at least minimized as the information contained in the header portion of the image contains the prescription (such as the horizontal and vertical resolution) for how to reconstruct the transmitted image from the received data.

To emphasize the need for image compression consider the following example. A digitized grey scale image consists of an array of picture elements (pixels) represented by numbers that correspond to the brightness (grey scale) of each pixel, with 0 = black and 255 = white. A grey-scale image has 1024×1024 such numbers taking integer values between 0 and 255. Thus the image is given by a matrix $(P_j)_{j \in \{0, \dots, 1023\}^2}$ with $P_j \in \{0, \dots, 255\}$. To encode this sample image would require a data file approximately one million bytes in size. Compression of this sample image with the appropriate image compression algorithm will facilitate the efficient and effective transmission of the image across a given communication system configuration.

For the ICPIIC effort the following three image compression techniques were utilized: the Graphics Interchange Format (GIF), the Joint Photographic Experts Group (JPEG), and Wavelet. GIF is a popular commercial standard 8 bit/256 color protocol for transmission and interchange of raster graphic data in a way that is independent of the hardware used in its creation or display. GIF is comprised of a lossless compression strategy based on LZW compression (Lempel-Ziv-Welch algorithm). The LZW technique was originally developed for compression of textual material, and compresses files by substituting commonly occurring character sequences with a reference to the first occurrence of the sequence. For fullscreen, 8 bit images of moderate

complexity, 4:1 compression is the average. Since this is a lossless compression scheme, the compression ratio can not be increased by trading off image quality.

GIF compression offers the following advantages and strengths:

- it is a lossless compression scheme for 8 bit images (since no image degradation occurs, repeated compression and decompression cycles are possible, also suitable for images where information loss can not be tolerated).
- it is ideally suited to stylized images such as line drawings, or those which contain only a limited number of colors (for these images it can produce good compression ratios).
- it is widely used and supported, with no runtime license required.

The weaknesses and disadvantages of GIF compression are as follows:

- it is not suitable for 24 bit images. When compressing such images, much of the color information is lost during the quantization process which reduces this to 8 bits. Good algorithms can however optimize this process so that the resultant image will still have good quality from a human point of view.
- the compression ratios are low. These can not be traded off against compression times or degree of loss of quality.
- it is not intended for moving images/video.
- it is not resolution independent.

JPEG is a lossy image compression scheme aimed at still images, in color or grey scale, and having some degree of complexity. The greater the compression ratio, the greater the degree of information loss. This can be user determined to optimize the trade-off between resultant image size and image quality. The JPEG compression algorithm exploits some of the ways in which the human eye perceives and analyzes images, so that compressed images still appear to be of high quality when looked at by human eyes. The total amount of time it takes to compress and decompress an image are symmetric, meaning that they take roughly the same amount of time.

The JPEG algorithm is based on the forward DCT (Discrete Cosine Transform), as applied to a block breakdown of the original image into 8 by 8 blocks, quantized down to a finite set of possible values, and then further transformed (run length encoding) and finally entropy encoded using Huffman or arithmetic coding.

The following list compares the compression ratios with the observed quality. A 20:1 compression ratio means that an image originally 900K will be compressed to 45K, which is one twentieth of its original size.

- 10:1 to 20:1 - High quality, with little or no observable loss in image quality to the human viewer.
- 30:1 to 50:1 - Moderate quality.
- 60:1 to 100:1 - Poor quality, suitable for thumbnails and previews. Marked blockiness and "Gibb's effect" occurs. The Gibb's effect is the name given to the phenomenon where disturbances and/or ripples can be seen at the margins of objects with sharp borders.

In comparison with GIF compressed images, high quality JPEG image compression produces an image 4 to 5 times smaller.

JPEG image compression offers the following advantages and strengths:

- it provides support for full 24 bit color images. In contrast, GIF compression only supports 8 bit images.
- the compressed image size and image quality trade-off can be determined by the user.
- it is ideally suited to images of real world scenes, or complex computer generated images.
- it is platform independent for displaying 24 bit images. It is currently the most widely adhered to image compression standard, with the algorithm, source code implementations, and public domain viewers readily available.

The weaknesses and disadvantages of JPEG are as follows:

- JPEG compression is a trade-off between the degree of compression, the resultant image quality and the amount of time required to compress and decompress an image. Also, blockiness results at the high image compression ratios.
- it produces poor image quality when compressing text or images containing sharp edges or lines (known as the Gibb's effect).
- it is not suitable for 2 bit black and white images.
- the degree of compression is greater for full color images than it is for grey scale images.
- it is not a suitable strategy for images that are still being edited, because every compression and decompression cycle causes a loss in information.

- it is not intended for moving images and/or video.
- it is not resolution independent. Does not provide for scalability, where the image is displayed optimally depending on the resolution of the viewing device.

Wavelet transforms are high compression algorithms capable of analyzing data at multiple resolutions (also known as "scale"). In other words, they cut up data into different frequency components, and then analyze each component with a resolution matched to its scale. In addition, transient events in the data are preserved by the analysis. When the wavelet transform is applied to a signal in the time domain, the result is a two dimensional, time-scale analysis of the signal. The transform of the data exhibits discrete steps in time on one axis, and discrete steps of resolution on the other. The wavelet transform has proven to be a useful tool for the compression and analysis of both signals and images. The discrete wavelet transform (DWT) is the wavelet transform as applied to a regularly sampled data sequence and the fast wavelet transform (FWT) is an efficient implementation of the DWT.

DWT has the distinct benefit of being able to perform the simultaneous localization of frequency and time. This gives the DWT the instantaneous advantage of information condensing. The wavelet transform reduces information in a signal roughly to averages and differences of neighboring pixels at discrete scale (frequency) levels. In an image, the information in areas of near constant color are collapsed into the average component and the difference components. Each average and difference component contains information about an area 4 times its size. If the differences are close to zero then the components can be discarded and all the information about the area will be contained in the average components.

The wavelet analysis procedure adopts a wavelet prototype function, called an analyzing wavelet or mother wavelet. In the FWT algorithm, the sampled data set is passed through scaling and wavelet filters. These filters are collectively known as a quadrature mirror filter (QMF) pair and are actually low-pass and high-pass filters which contain complementary bandwidths. The outputs of both filters are decimated (desampled) by a factor of two. The high-pass filtered data set is the wavelet transform detail coefficients at the same level of scale as the transform. The low-pass filtered data set is the approximation coefficients at the same level of scale. Temporal analysis is performed by using a high-frequency version of the prototype wavelet, while frequency analysis is performed with a dilated, low-frequency version of the same wavelet. Due to the decimation, both sets of coefficients have half as many elements as the original data set. The approximation coefficients can now be used as the sampled data input for another pair of wavelet filters, identical to the first pair, generating another set of detail and approximation coefficients at the next lower level of scale. This process can continue until the limit for the unit interval is reached. Because the

original signal or function can be represented in terms of wavelet expansion (using coefficients in a linear combination of the wavelet functions), data operations can be performed using just the corresponding wavelet coefficients. Further compression is achieved by keeping only the most significant bits of the coefficients which is known as scalar quantization.

Threshold coding is the process whereby only those coefficients that exceed a specified threshold are retained. Threshold coding results in the sparse representation of the data which makes wavelets an excellent tool for data compression. Optimally, the coefficients are transmitted in order of decreasing size. The process of sending coefficients sequentially across a communication link to allow for the gradual reconstruction of the image is known as progressive transmission. Flexibility is a characteristic that makes the FWT an important tool for image transmission. The FWT lends itself ideally to applications which require reordering of digital information. Its adaptability is best seen in the progressive transmission of an image over a digital data link where incoming information builds on that already received, resulting in no computational or information overhead. In other words, the time and information it takes to decompress an image piecewise is the same as decompressing the image all at once.

As stated previously, the JPEG image compression method is based on a division of an image into blocks of 8×8 pixels, after which each block is transformed with a discrete cosine transform. While the JPEG method performs well at high or medium bit rates, it introduces perceptibly annoying blocking artifacts (due to block-wise transform coding) at low bit rates. The performance of JPEG deteriorates rapidly at compression ratios above 30:1. Due to good localization in both space and frequency domains of the basis function, the wavelet transform can obtain greater compression ratios thereby facilitating high data throughput which is required for real-time/video and image compression. As a result, the reconstruction quality of wavelet compressed images has moved well beyond the capabilities of the JPEG method.

1.2 Error Correction and Detection

When information is propagated between two points, errors are introduced due to noise along the propagation channel. Two things are therefore necessary; error detection, and (if possible) error correction.

The simplest form of error correction is to use an error-detecting code so conceived that any false or incorrect signal initiates a repetition of the transmitted character that was incorrectly received. This form increases not only the transmission time, but also the probability of signal detection and interception when this may be an issue of concern.

A better method is to divide the data into packets of fixed size, where each packet contains image information and a code that allows a user to detect, with high probability, if an error has been introduced. Based upon the known size of the data packet (N), and the number of bits of information (k), it is usually possible to remove the errors and reconstruct the original image.

SPW provides a number of EDAC algorithms, such as Reed-Solomon and Bose-Chaudhuri-Hocquenghem (BCH) which includes a vector BCH encoder and decoder. BCH encoding and decoding processes binary data in blocks. The convolutional encoder, which is often used with Viterbi decoders, typically works with arbitrarily long, continuous flowing bit streams. The Viterbi algorithms have also provided competitive performance with blocks of data. SPW provides both the hard and soft decision versions of the Viterbi decoding algorithm, with the soft decision version permitting substantially fewer residual errors. Viterbi decoding is the most commonly used form of trellis decoding, and requires substantially less storage of prior data than sequential decoding. Many satellite communications systems use Viterbi decoding.

Reed-Solomon encoding and decoding is well suited for use with M-ary signaling, and also for error distributions that are uniform in the symbol space. JTIDS uses Reed-Solomon coding. Included in the SPW software are vector Reed-Solomon coding and decoding and included in the ICPIC module libraries are M-ary modulation and demodulation to complement the Reed-Solomon coding modules.

In addition, TCM and V.32 encoders and decoders are available as part of the ICPIC module libraries. V.32 coding is an ISO standard for telephone line transmission.

1.3 Propagation Channel

The propagation channel describes the interaction between the signal and the environment between the transmitter and receiver. Among the channel models incorporated into ICPIC are noise, interference, tapped delay, and path loss.

The term background refers to additive contamination of the communication signal and includes both noise and interference. Noise is generally natural in origin and broadband, and includes thermal receiver noise and environmental or atmospheric noise due to natural electromagnetic effects. Interference is generally man-made and often narrowband. Table 1-1, Independent Parameters in Background and Channel Models, shows the occurrences and properties of the independent parameters used in background and channel components.

Independent Parameter	Occurrence	Relationships
Configuration center frequency	Random Interference HF Interference VHF Interference	Typically inside signal band
Configuration bandwidth	Random Interference HF Interference VHF Interference	Interferers outside detector input bandwidth have no effect on vulnerability
Configuration input file Name of file used to store random interference configuration	Custom Interference	Format same as configuration output file read by Custom Interference module
Configuration input file Name of file used to store random interference configuration	Random Interference	Format same as configuration output file read by Custom Interference module
Input SNR	Gaussian Noise Gamma Noise	Assumes only one noise source in use
Exponent describing power loss with propagation distance	Path Loss	
Frequency Resolution Spacing of grid of candidate interferer carriers	Random Interference	Less than configuration bandwidth
Minimum interferer width	Random Interference	Less than maximum interferer width
Maximum interferer width	Random Interference	Greater than minimum interferer width
Mean Power (dB above signal)	Random Interference	
Number of Interferers	Random Interference	Integer, at least one
Power standard deviation (dB)	Random Interference	Greater than one tenth of the mean interferer power
Scale factor Controls strength of Cauchy noise, which has infinite variance	Cauchy Noise	Input SNR is not defined
Spread Time interval between first and last taps	Tapped Delay	Less than interception collect time
Transmitter to communication receiver distance	Path Loss	
Transmitter to interception detector distance	Path Loss	

Table 1-1 Independent Parameters in Background and Channel Modules

ICPIC includes three zero mean, white noise sources: Gaussian, Gamma and Cauchy. The variance of discrete samples of the complex envelope of noise depends on the sampling frequency and power spectral density of the real noise, as shown in Appendix A. The Gaussian and Gamma noise modules are parametrized by the input SNR (Signal-To-Noise) ratio under the assumption that the two modules are used as alternatives, and not together.

The Gamma Noise module permits simulation of non-Gaussian effects and produces radically symmetric complex noise whose magnitude is a gamma variable. The marginal distributions of the real and imaginary components are not expressible as elementary functions, but decay exponentially. The only independent parameter is the input SNR and dB.

Cauchy noise represents heavy-tailed noise distributions and is an exceptional case, because it has infinite variance. The Cauchy Noise module produces radially symmetric complex noise whose real and imaginary components are marginally distributed as Cauchy random variables. The user may set a scaling parameter which multiplies a standard unit variable. The Cauchy variable has an undefined mean and infinite average power, so that signal to noise ratio has no meaning. Instead, Cauchy Noise is parameterized by a scaling factor.

The interference module provides the user with three options with which they may configure the module with an arbitrary number of interferers, with variable widths, powers and frequencies.

The Random option allows the user to specify the number of interferers, the mean and variance of the interferer powers, and the maximum and minimum interferer widths, and the maximum and minimum interferer carrier frequencies. A configuration of the interferers is then randomly generated from the specified distributions. The frequency and bandwidth of each interferer are generated from uniform distributions, and the power of the interferers are generated from a log-log distribution on analysis of empirical observations as given in Appendix B. The interferer width is implemented by BPSK (Binary Phase Shift Keying) modulating each interference carrier at a modulation frequency equal to half the interferer width.

The Custom option allows the user to directly specify the frequencies, widths, and powers of the interferers. The user is given the capability to specify the number of interferers; the configuration center frequency; the interferer center frequencies, expressed as offsets from the configuration center frequency; the interferer powers, in dB above the communication signal power; and the widths of the interferers. The bandwidth is implemented by BPSK modulating each interference carrier at a modulation frequency equal to half the bandwidth.

The HF and VHF options allow the user to select stored interference configurations typical of the HF and weak, medium and strong VHF bands. An interference background generated from a stored configuration chosen to be characteristic of typical operating environments is added to the signal. The user selects the center and width of the operating band, and the modules generate the interferers which lie in the selected band.

The channel category models phenomena which delay or distort the signal or change its power, such as multipath, propagation losses, and Doppler shifts.

A custom coded tapped delay line provides a foundation for channel modeling. The output is a linear combination of delayed versions of the input with constant weights specified by the user. The independent parameter is the total delay spread. The number of taps is equal to the product of the delay spread and the sampling frequency, and the user may specify arbitrary tap weights.

If the communication receiver and interferer are at different distances from the transmitter, the interferer will have a range advantage or disadvantage relative to the communicator. The Path Loss module models the loss with a power law decay of signal power as a function of propagation distance.

1.4 Interaction Between Compression, EDAC and Channel Model

EDAC techniques introduce delays due to processing, retransmission, and associated buffering, and each of these effects can have important system design implications. The designer must take into account how long an average transmission will take, the requirements for real-time image display, the tolerance on errors, transmit protocol, and how much buffering memory is available. EDAC effectiveness may be sensitive to the portion of the compressed image to which it is applied based upon the specific compression algorithm being used. For example, it may be necessary to completely eliminate errors from the image header. The errors themselves are a function of the noise model and its magnitude. An accurate assessment of these combined effects is necessary in order to characterize system performance and optimize the system design. This is the functionality that the ICPIC workstation testbed provides.

2.0 An Example Of An End-To-End Simulation

This section describes how to set up an ICPIC simulation. The process is divided into SPW and non-SPW steps. The SPW steps involve building the actual simulation using the Block Diagram Editor (BDE) of SPW, and the non-SPW steps generate the input and analyze the output signal. The tradeoff between using the custom coded modules of the ICPIC environment or off-line analysis modules is discussed in Section 2.5.

2.1 Building The Simulation

Building a SPW simulation requires care in accounting for module-specific requirements. It is often possible to build the same simulation in slightly different ways that differ drastically in computational efficiency. Consider the simulation shown in Figure 1, which models the transmission of an image using BPSK modulation, BCH encoding, with the addition of White Gaussian Noise. This diagram is divided into eight sub-blocks for the purposes of this discussion. We will discuss each block and (where appropriate) possible alternatives and tradeoffs.

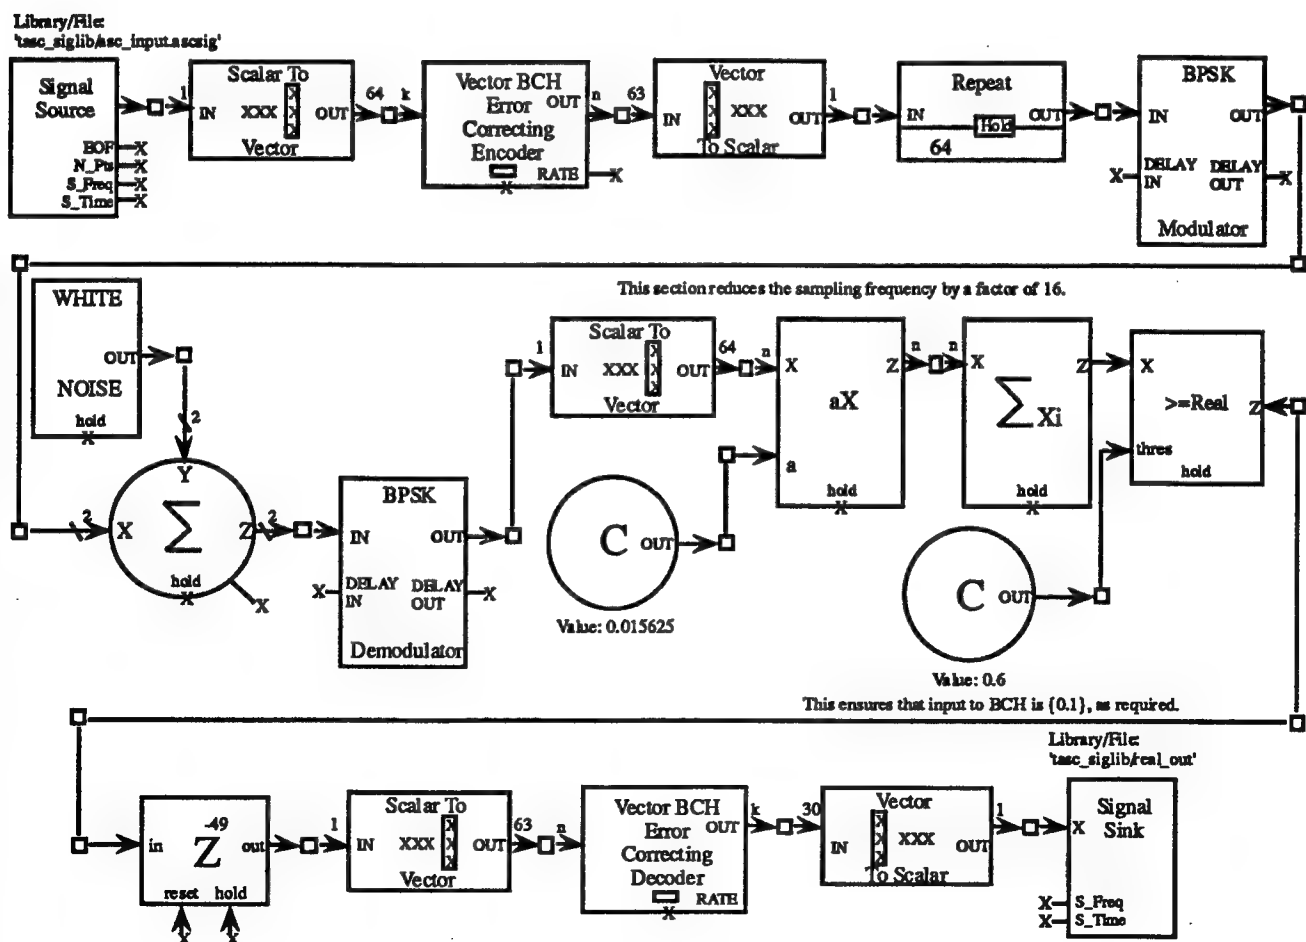

Figure 1: BPSK BCH Communication Model

Block 1: Signal Source

This defines the input signal, which is in SPW format. This is defined by a 12-line header and data, an example of which is shown in Figure 2. The details of this file and how it is generated from an image will be discussed in Section 2.2.

The Signal Source block, besides defining the input signal, displays it in the Signal Calculator module of the SPW.

```

```

Figure 2: Sample SPW File

Block 2: Vector BCH Encoder

In this simulation we used a word size of $N=63$, and a data length of $k=30$, to give k/N close to $1/2$. Contrary to the SPW documentation, the allowable values of k and N are not arbitrary. Figure 3 gives the allowable (k, N) pairs¹.

Since each block of 30 data points is being encoded into a 63-data length word, SPW requires that the Vector BCH Encoder block be fed in 30-data chunks. This is achieved with a *Scaler To Vector* block, which takes every 30 data points and transforms it into a 30×1 vector. The output from the BCH encoder is a 63×1 vector which is converted back into set of 63 scaler points with a *Vector To Scaler* module.

N	k
7	4
15	5, 7, 11
31	6, 11, 16, 21, 22
63	7, 10, 16, 18, 24, 30, 36, 39, 45, 51, 57

Figure 3: Allowable (N, k) Pairings For BCH Module

Alternative Block 2: Scaler BCH Encoder

This simulation originally attempted to use a scaler BCH encoder. This required that each data point be repeated 63 times. The result was an unacceptably long run time and storage requirements that were quickly exceeded by images files larger than 25 kbytes. These severe restrictions were removed by using the Vector BCH Encoder

It should be mentioned that the vector BCH encoder/decoder modules are not mentioned in the SPW Communication Library Reference.

Block 3: Repeat Block

The *Repeat* block takes each scaler input and repeats it the specified number of times (16 in this case). That is, if the sequence $\{1, 0, 1\}$ is input into a *Repeat* block with a repeat factor of 3, the output would be $\{1, 1, 1, 0, 0, 0, 1, 1, 1\}$. Adding a Repeat block is equivalent to sending each data point a repeat factor number of times. This adds redundancy to the data and decreases the effect of channel noise by allowing it to be averaged out by Block 5. It was found that for $S/N < 20$, BCH encoding was not sufficient, by itself, to remove the effects of noise.

¹ The SPW Communications Library Reference states that N is $2^m - 1$, where $2 < m < 9$ and $0 < k \leq N$ is arbitrary within this range. In fact, k and N are restricted to the discrete pairings shown in Figure 3.

This brings up an important point about transmission frequency. The transmission frequency is not an explicit input parameter, but is effectively set to unity. As far as this simulation is concerned, it does not care what the frequency is, as there is no frequency-dependent module in this simulation. If we were to model the transmission frequency (typically 9,600 baud) explicitly, then each data point would have to be *Repeated* with a factor equal to the frequency. This would require prohibitively long simulation times and disk space requirements. We were therefore forced to model equivalent systems with manageable frequencies.

If the system being modeled operates at a frequency of v _Hz and a repeat factor of R , then the effective frequency is v/R Hz since each data point needs to be transmitted R times.

Block 4: Modulator/Channel/De-Modulator

The encoded signal (consisting of zeros and ones) is BPSK-modulated and propagated through a channel. In this case, the channel is modeled as additive white Gaussian noise, with the addition performed by the Σ _module. Once propagated, the signal is then de-modulated and fed into an averager. The BPSK modulator/demodulator and the White Gaussian Noise blocks are custom-coded routines.²

Block 5: Noise Removal By Averaging

This block takes each segment of R -repeated data and averages it to get a single number. Remember that each block of R data points output from the decoder represents a single number; if noise were not present, then all these numbers would be identical. The average is performed by converting each block of R numbers into a vector, multiplying the vector by $1/R$ (with the aX block), and then summing the elements of the vector (Σx block). The constant $1/R$ is stored in the *Scaler Constant* block (C).

Block 6: Decision Block

Since the data consists of zeros and ones (as dictated by BPSK modulation), a check is performed to determine if the output from the averager exceeds some threshold. This threshold is stored in another constant block. If the average value exceeds this threshold then a one is output, if not, a zero is output. The threshold generally increases with decreasing S/N since noise in this simulation can only increase the signal strength. The actual value of the threshold is determined by trial and error.

² Curiously, the SPW Communications Library has its own BPSK modulator, but not a BPSK demodulator module.

Block 7: Delay

The BPSK modulator/demodulator modules (Block 4) introduce a time delay into the signal. This must be accounted for in order that the BCH decoder (Block 8) be properly synchronized with the signal. Otherwise, the decoder will operate on segments from two separate signal code words (of size N), rather than a single code word. The size of the delay is $N-1$.

The delay can be seen by placing *Signal Sinks* before the BPSK modulator and after the BPSK demodulator (before and after Block 4) with a large S/N value in the *White Noise* module (or equivalently with the noise module disconnected). The two signals will appear identical, but phase-shifted. This test should always be done before using any ICPIC system configuration in order to insure an accurate baseline.

Block 8: Vector BCH Decoder

This block is analogous to Block 2, except the numbers are reversed since the signal is being decoded. The same comments mentioned in Alternative Block 2 apply here as well.

Block 9: Signal Sink

The Signal Sink is where the received signal is stored. From the Signal Calculator module of the SPW the received and input signals can be viewed and manipulated. For example, the difference signal, mean, error, and bit error rate can be determined using the functionality of the Signal Calculator.

2.2 Constructing The Input Signal

The input signal is constructed from an image file which can be in any format. The basic procedure is to read the image file, one bit at a time, and convert each bit into a binary representation. Since a bit is 8 bytes, each bit is converted into an 8-digit binary number. The program that does this is called **build_spw** and is invoked by typing:

```
build_spw image_file
```

where *image_file* is the name of the image. The output is an ASCII file called **spw_in.asc**, which consists of a 12-line header followed by the binary-translated data. Each digit of each data point is placed in column 1 of each line after the header, as illustrated in Figure 2.

Once this file is created, it needs to be transferred to the appropriate SPW directory, which is called *local_path/altadata/spwdata/signal_lib/*, where *local_path* is the location of the top-level SPW directory, and *signal_lib* is the (arbitrary) name of the signal library where the user SPW signal files are stored. An example of *local_path* is */export/home/delmedico/*. This transfer is accomplished by typing:

transfer

from the C-shell command line. **transfer** is a script that takes **spw_in.asc** and copies it to a file called **asc_input.asc** in the appropriate SPW directory. This script needs to be edited before using it the first time in order to modify *local_path* for your specific system.

2.3 Wavelet To SPW File Format Conversion

Since wavelet compression is not a standardized technique, and there are many different wavelet routines available, transforming a wavelet file to SPW format is a special case since we have to create the wavelet file in the first place. After much searching, we found the best package to use was **DSW**; this is a descendant of the David Sarnoff Labs wavelet package and is used by many government and private organizations. A limitation of **DSW** is that it only converts TGA image files to a wavelet representation. TGA is one of the earlier image storage formats that has the benefit of being easy to decode. To remove this limitation, we used the publicly-available **pbmplus** graphics file conversion package which allows conversion among most graphics file formats. **pbmplus** consists of a set of routines to convert from one format to another using intermediary formats. Using **bold** to represent executable programs, and unbold to represent file formats, the procedure for converting from GIF to wavelet and finally to SPW is:

GIF ==>giftoppm ==>PPM ==>ppmtotga ==>tga ==>DSW ==>wavelet file ==>build ==>SPW .

Alternatively, the starting point could have been TIFF or BMP, or another graphics format other than GIF. **pbmplus** does not have any JPEG conversion routines, so in this case we would use another public-domain program called Xview, which is invoked by typing **xv** at the command prompt. From here a JPEG file can be opened and saved in a GIF format and then converted using **gif2wav**. This entire process can be invoked with a script by typing:

gif2wav gif_filename

where *gif_filename* is the name of the GIF file with the extension *.gif* assumed.

2.4 Data Analysis

The output signal can be analyzed within the Signal Calculator or from the UNIX command-line. From within the Signal Calculator you can;

1. Visually compare the input and output signals
2. Calculate and view the difference signal
3. Calculate statistics on the difference signal, such as mean, variance, and number of errors.

From the command line, a tool is provided to calculate all the quantities in Item 3 above, with the added convenience of batch mode processing. SPW provides a mechanism for batch mode processing a simulation when only one input parameter changes. In this way a user can parameterize the output statistics as a function of S/N, with all other variables kept constant. Each output is automatically stored in a separate file which can be parsed and fed into the command-line analysis code.

The code that calculates the output signal statistics is called `rms` and is invoked from the command line by

`rms spw_output_filename`

where *spw_output_filename* is the output from SPW that is stored by Block 8 in Section 2.1.

The output from `rms` will be discussed in more detail in Section 3.

2.5 Reconstructing And Viewing The Transmitted Image

Although not a quantitative measure, the most intuitive way of judging how well the transmitted signal was received is to view the transmitted and received images side by side. This requires that the raw data from the *Signal Sink* (Block 8 in Section 2.1) be reconstructed to form an image file. This is accomplished by typing:

`getdata`

from the UNIX command line; this takes the ICPIC/SPW output file from the SPW signal library directory and places it in the user's working directory. As with the `transfer` script (Section 2.2), `getdata` needs to be edited before using it the first time in order to change the relevant path names. `getdata` takes the outfile file called `real.out` and copies it to the working directory as `spw.out`.

The data in `spw.out` is then reconstructed into an image file by typing:

build

from the UNIX command line. **build** takes each block of 8 lines past the 12-line header file, which consists of zeros or ones³, treats it as an 8-bit binary number, and converts it back to an 8-bit decimal integer (0 - 255).

The analysis program (**rms**) uses the same procedure to convert from binary to decimal numbers. To do otherwise would ignore the implicit weighting of the binary digits. The outputs from **rms** are the number of bit errors (this is based on the binary representation), the RMS error between the original image and the output from ICPIC/SPW, and a quantity called the Contrast Error. This is basically a normalized RMS, where the normalization is the average pixel value of the image.

Once the image file is reconstructed, it can be displayed using **xv**. In some versions of **xv**, it is possible to display multiple files side by side. In other versions only a single file can be displayed; in this case **xv** must be invoked twice, once for the original and once for the reconstructed image. If the S/N ratio of the Gaussian noise is too low, then **xv** may not recognize the image as a valid format (it can handle most of them) and will not be able to display it.

3.0 Sample Output

The GIF image shown in Figure 4 was used to study the effects of varying the encoder parameters (k , N) and S/N. It has sufficient detail to show any deviations from the original and is small enough (19.2 Kb) to allow quick turn around times (under 10 minutes/run).

Figure 4: Book graphic test image

³ This is guaranteed by the Decision Block (Block 6 of Section 2.1).

Figure 5 shows plots of the Contrast Error for three (k, N) values. For all cases the transmitted image was identical to the original for $S/N > 15$ dB. For 7/63 coding (7 information bits in a code word of 63 bits), the transmitted image is identical to the original for S/N as low as 5 dB.

Figure 5: Variation Of Contrast Error With S/N

Notice that as S/N tends to zero, the error does not tend to infinity. The reason is that the decision block (Block 6) forces the input to the decoder to be zero or one. As such, as S/N decreases, the output saturates to all ones (totally black image). This represents the maximum deviation from the original image, and also points out that this deviation is image-dependent. For example, if the image had been mostly black, then the contrast error would have been smaller for the same system parameters. This same behavior was seen when looking at the fraction of incorrect bits in the received image.

Figure 6 shows the signal before and after Block 4, respectively, for the case of no noise. This illustrates the phase shift (ϕ) introduced by the BPSK modulator/demodulators, and illustrates the need for the delay module (Block 7). The delay is set to $N - \phi$ sample points. If the delay block is not added to the system, then the BCH decoder will receive segments from two consecutive code word blocks, rather than a single code block of 63 bits. An indication of an incorrect delay value is a deviation between the transmitted and original image when no noise is present. This test case should always be performed before attempting any tradeoff studies.

Figure 7 shows the signal before and after Block 4 with $S/N = 5$. The two signals are now clearly different, but all the deviations (except for the phase shift) are accounted for by the BCH decoder for $k=7$ and $N=63$.

Figure: 6: Signal before (top) and after BPSK modulator block without noise. The signals are identical, except for a phase shift.

Figure: 7: Same as above, but with noise added ($S/N = 5$). The signals are now different, but this is corrected by the BCH decoder for $K=7$ and $N=63$.

4.0 Summary

ICPIC provides a flexible environment that gives the user the capability of modeling various communication channels, error detection and correction techniques (EDAC) and modulation types, as well as the ability to assess their effect on imagery compressed with various algorithms. Software tools are provided to convert any type of image (including wavelet) into a SPW format, and to convert from one image format to another. Changing the channel and EDAC models is accomplished by dragging and dropping operations in the BDE (Block Diagram Editor) and then setting the appropriate parameters for each module.

The image preparation and analysis tools were developed off-line from ICPIC/SPW to run from the UNIX command line. This was found to be a much more efficient approach than to force everything within the ICPIC/SPW framework. Included in these off-line software tools is the capability to reconstruct the received image from the ICPIC/SPW output. Depending on the errors in the received image, graphics viewers (such as xv) may not be able to display the reconstructed image. This is especially true if errors occur in the header file. One approach to minimize header errors is to agree on a particular fixed header, and then only send the actual data. It is also possible to develop robust image viewers that attempt to correct for corrupt data. These issues should be investigated in the future.

To date ICPIC's analysis capabilities have been applied to simplex communications channels. These are one-way channels where the receiver does not have the capability to request re-transmission of data missed due to channel bit-errors. Simplex channels are primarily used today in the tactical arena. These are situations in which the receiver does not want to turn on a transmitter out of fear of detection by hostile forces or alternatively for portability reasons the receiver sight lacks sufficient power for transmission. UHF satellite channels, such as FLTSAT, are a good example of channels used primarily for simplex communications. The application of the developed capability to evaluate the performance on compressed imagery of channels such as these could also be an area for future investigation.

Another area for investigation is how to specify quality of service and to best evaluate the results of channel induced corruption on compressed imagery. Quantitative comparison (RMS error, etc.) of the reconstructed corrupted images and original images can often be misleading. Qualitative comparison by side-by-side viewing of the reconstructed corrupted image and original image is often more useful but is subjective. The basic problem is that of objectifying a basically subjective phenomena. In addition, the performance depends on the particular scenario. For example, is the goal to pick out a rocket launcher in the woods, or to distinguish between classes

of tanks? It may be acceptable to use much higher S/N ratios to answer the first question and this may effect the final choice of system operating parameters.

The fact that extremely corrupted images cannot be decompressed at all for viewing leads to yet another area for future investigation. Since an image that cannot be decompressed is useless, it is desirable to conduct more detailed tradeoff studies with more complicated channel models, better imagery and different compression algorithms in order to investigate the error threshold for "decompressibility" for different EDAC methods and compression algorithms. This could be accomplished for various channels and modulation types. The goal would be to document which EDAC methods, modulation types and compression algorithms are best suited to getting a decompressible (and hopefully viewable) image through under various channel conditions.

These are significant issues that need to be fully addressed, and ICPIC/SPW provides the framework to address them.

Appendix A

Complex, Sampled, White Noise

Waveform simulations generally process discrete samples of continuous waveforms. In the case of white noise a continuous waveform is not available to sample, so random discrete sequences are generated directly, and a method is needed to set the parameters of the generating probability distribution. The chosen method is to require the discrete simulation of transmitted power through any filter to match exactly the transmitted power in the corresponding continuous process.

Complex envelopes are processed so that real white noise, which cannot be expressed in terms of quadrature components, are modeled as real bandpass white noise n with a power spectral density given by

$$S_n(f) = \begin{cases} S_0 & |f - f_{ces}| < B/2 \\ 0 & \text{otherwise} \end{cases} \quad (\text{A-1})$$

where f_{ces} is the signal center frequency, and B is much larger than the largest bandwidth being simulated, but less than $2f_{ces}$. The complex envelope $z(t)$ of $n(t)$ relative to f_{ces} has a power spectral density given as

$$S_z(f) = \begin{cases} 2S_0 & |f| < B/2 \\ 0 & \text{otherwise} \end{cases} \quad (\text{A-2})$$

and the quadrature components x and y have identical power spectra:

$$S_x(f) = S_y(f) = S_z(f) \quad (\text{A-3})$$

Each quadrature component is modeled by a discrete random sequence with variance determined by the criterion that the noise power transmitted through any real lowpass filter acting as the noise baseband can be accurately modeled by the discrete simulation. If the quadrature component x is passed through a filter with transfer function $H(f)$ and real impulse response function $h(\tau)$, the transmitted power is:

$$P = E \left\{ \left(\int_{-\infty}^{\infty} x(t - \tau) h(\tau) d\tau \right)^2 \right\} \quad (\text{A-4})$$

Expanding the square as the product of two integrals and taking the expectation of the integrand gives:

$$P = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_x(\tau_2 - \tau_1) h(\tau_1) h(\tau_2) d\tau_1 d\tau_2 \quad (\text{A-5})$$

where $R_x(\tau)$ is the autocorrelation function of x . Expressing $R_x(\tau)$ as the Fourier transform of S_x and using (A-2) and (A-3) gives:

$$P = 2S_0 \int_{-\infty}^{\infty} |H(f)|^2 df \quad (\text{A-6})$$

In a discrete simulation (A-5) becomes:

$$P_{discrete} = f_{sa}^{-2} \sum_{i,k} R_x\left(\frac{i-k}{f_{sa}}\right) h\left(\frac{i}{f_{sa}}\right) h\left(\frac{k}{f_{sa}}\right) \quad (\text{A-7})$$

which simplifies, since the discrete random numbers are uncorrelated, to

$$P_{discrete} = f_{sa}^{-2} \sigma_x^2 \sum_i h^2\left(\frac{i}{f_{sa}}\right) \quad (\text{A-8})$$

where

$$\sigma_x^2 = R_x(0) \quad (\text{A-9})$$

is the variance of the discrete time sequence modeling the x -component. For large sample frequency the sum in (A-8) approximates an integral, giving:

$$P_{discrete} \cong f_{sa}^{-1} \sigma_x^2 \int_{-\infty}^{\infty} |h(\tau)|^2 d\tau \quad (\text{A-10})$$

so using the norm preserving property of Fourier transforms gives:

$$P_{discrete} \cong f_{sa}^{-1} \sigma_x^2 \int_{-\infty}^{\infty} |H(f)|^2 df \quad (\text{A-11})$$

Comparing (A-11) to (A-6) and requiring the discrete simulation to model the continuous process accurately means the variance of the discrete quadrature component must be given by:

$$\sigma_x^2 = 2f_{sa}S_0 \quad (\text{A-12})$$

while (A-3) shows both quadrature components have the same power so,

$$\sigma_x^2 = \sigma_y^2 = 2f_{sa}S_0 \quad (\text{A-13})$$

The intended communicator's input signal-to-noise ratio is a dimensionless quantity that is of greater interest to the user than noise variances of power spectral densities. For communication signal power equal to unity shows the input signal-to-noise ratio is given by:

$$(S/N)_i = \frac{1}{f_{da}S_0} \quad (\text{A-14})$$

Combining (A-13) with (A-14) gives:

$$\sigma_x^2 = \sigma_y^2 = \frac{2f_{sa}}{f_{da}(S/N)_i} \quad (\text{A-15})$$

which is built into the white Gaussian noise block so the independent parameter set by the user is the communicator's input signal-to-noise ratio.

Appendix B

Interference Power Distributions

Interference environments change dramatically with geographical location, season, time of day, and frequency band, and while trends have been established [1], many of the details of the environments remain unpredictable. To model the multiplicity of unpredictable environments a Random option is available which randomly generates a configuration of interferers, subject to probability distributions whose parameters are specified by the user. Empirical observations reported and analyzed suggest the use of a specific distribution of interferer powers. Simplifying the distribution and parameterizing in terms of the mean and variance of the interferer powers enhances the Random option's ease of use.

The probability distribution used is

$$F(p) = \begin{cases} 0 & p < P_{\min} \\ 1 - Cp^{-d} & P_{\min} < p < P_{\max} \\ 1 & p > P_{\max} \end{cases} \quad (\text{B-1})$$

and gives the probability that a randomly chosen interference line will have power less than p . Interferer powers are measured in units of the signal power at the communication receiver, so p is the ratio of interferer power to signal power. For simplicity P_{\max} will be taken to approach infinity, and P_{\min} will be chosen so that $F(p)$ approaches zero continuously at P_{\min} , which requires $1 - Cp_{\min}^d = 0$, so

$$P_{\min} = C^{1/d} \quad (\text{B-2})$$

Differentiating (B-1) gives the probability density as

$$f(p) = \begin{cases} 0 & p < P_{\min} \\ Cdp^{-d-1} & p > P_{\min} \end{cases} \quad (\text{B-3})$$

The mean power is given by

$$\mu = \int_{P_{\min}}^{\infty} pf(p) dp \quad (\text{B-4})$$

and using (B-3) and evaluating the integral gives:

$$\mu = \frac{Cd}{d-1} P_{\min}^{1-d} \quad (\text{B-5})$$

provided

$$d - 1 > 0 \quad (B-6)$$

otherwise the density in (B-3) has infinite mean. The variance is given by

$$\sigma^2 = \int_{p_{\min}}^{\infty} p^2 f(p) dp - \mu^2 \quad (B-7)$$

and using (B-3) and evaluating the integral gives:

$$\sigma^2 = \frac{Cd}{d-2} p_{\min}^{2-d} - \mu^2 \quad (B-8)$$

provided

$$d - 2 > 0 \quad (B-9)$$

otherwise the density in (B-3) has infinite variance. Using (B-2) to eliminate p_{\min} from (B-5) and (B-8) gives

$$\mu = \frac{d}{d-1} C^{1/d} \quad (B-10)$$

and

$$\sigma^2 = \frac{d}{d-2} C^{2/d} - \mu^2 \quad (B-11)$$

Solving for the parameters C and d in terms of the mean and variance proceeds by using (B-10) to eliminate C from (B-11) giving:

$$d^2 - 2d - \frac{\mu^2}{\sigma^2} = 0 \quad (B-12)$$

and taking the positive root gives:

$$d = 1 + \sqrt{1 + \frac{\mu^2}{\sigma^2}} \quad (B-13)$$

and rearranging (B-10) gives:

$$C = \left(\frac{(d-1)\mu}{d} \right)^d \quad (\text{B-14})$$

Comparing (B-13) with (B-9) shows that as the standard deviation of the distribution becomes much larger than the mean $\mu^2 / \sigma^2 \rightarrow 0, d \rightarrow 2$ and the distribution approaches a singular limit.

The user supplies the mean power E_p and the power standard deviation s_p in dB so

$$\mu = 10^{E_p/10} \quad (\text{B-15})$$

and

$$\sigma = 10^{s_p/10} \quad (\text{B-16})$$

(B-15) and (B-16) in (B-13) and (B-14) are used to supply the coefficient values to the distribution in (B-1), and then randomly generate the interferer powers.

Appendix C

ICPIC Modules

The following list of entries uses a format based on the Unix man pages, this format provides easily accessible documentation of the modules included in the ICPIC workstation testbed. The modules are ordered alphabetically by component categories. The entry for each module provides a functional description of each module, the path leading to the module when using the SPW module selection under the "logical grouping" option, the input and output ports, and the parameters in the module.

There are two fundamental types of modules, known in SPW parlance as "custom-coded" modules and "multi-level" modules. The former refers to modules developed from scratch in C code. These are designated in the documentation by "Coded in C". Modules not indicated as such are multi-level. These are typically subsystems built from lower-level modules such as SPW primitives, custom-coded modules, or even lower level multi-level modules.

8Ary DS SPREADER

DESCRIPTION

Multiplies the complex input by an 8-fold complex pseudonoise sequence with a chip rate specified by the user as a multiple of the data rate. If the input signal has constant unit magnitude, the output power is 1. Delays the output signal by the input delay value for automatic synchronization. Outputs the spreading sequence as a global output connector called 'code'.

ADAPTIVE THRESHOLD EXCISION CORE

DESCRIPTION

Combines the two input vectors to form a complex vector, and removes the components with squared magnitude greater than an exceedance factor times a mean square magnitude. The mean square magnitude is of all the bins except a number of strongest bins. The user specifies the length of the vectors, the number of strongest bins to be excluded from the calculation of mean square magnitude, and the exceedance factor. The spectral resolution, or bin size is the sampling frequency divided by the dimensionality. The algorithm recomputes the threshold for each successive block of data and so adapts to changing background levels.

AGILITY

DESCRIPTION

Produces trigger pulses separated in time by random intervals called blocks. The user specifies the upper and lower bounds of a uniform distribution; each sample of the uniform distribution is rounded to the nearest multiple of the data symbol duration; and the result is used as the current block length. Setting an integer flag to 1 stores the trigger pulses and block durations as signals for subsequent inspection in SDE.

BANDPASS CYCLIC SPECTRUM

DESCRIPTION

Computes the bandpass component of the cyclic spectrum of a complex signal in SDE. The cyclic frequency of the bandpass cyclic spectrum computed is entered as an offset from twice the assumed carrier frequency. The spectrum is computed for spectral frequencies between $-f_{sa}/2$ and $f_{sa}/2$ where f_{sa} is the sampling frequency.

MENU PATH

SDE: SYSTEM/MACRO/EXECUTE/vmlib/Cyclic_bandpass

PARAMETERS

numsig	Display number of signal to analyze
alpha	Cyclic frequency desired
samp_freq	Sampling frequency
numpts	Number of samples to use in the computation
numffpts	Number of points in the FFT (must be a power of two)

LIBRARY / FUNCTION

CAUCHY NOISE

DESCRIPTION

Produces radially symmetric complex noise whose real and imaginary components are marginally distributed as Cauchy random variables. The user may set a scaling parameter, which multiplies a standard unit variable. The Cauchy variable has an undefined mean and infinite average power, so that signal to noise ratio has no meaning. If the scaling parameter is α , the marginal probability densities of the real and imaginary parts are given by

$$\frac{1}{\pi\alpha} \frac{1}{1 + (x/\alpha)^2}$$

MENU PATH

CHIP RATE AGILITY

DESCRIPTION

Outputs trigger pulses at a rate which varies pseudorandomly from one block of time to the next, but is constant within each block.

MENU PATH

Spread Spectrum > Chip Rate Agility

INPUT PORT

None

OUTPUT PORT

OUT Complex

PARAMETERS

min_duration	Minimum block length
max_duration	Maximum block length
nchav	Average number of chips per data symbol
hw	One sided percent chip length fluctuation
sfreq	Sampling frequency
fda	Data rate
Store_agility	1 to store trigger pulses and block lengths, 0 otherwise

LIBRARY / FUNCTION

walib/chip_rate_agty

CHIP RATE AGILE 8ary DS SPREADER

DESCRIPTION

Multiplies the complex input by an 8ary complex pseudonoise sequence, which has a rate that remains constant over blocks of time and varies pseudorandomly between blocks. The chip rate agile DS spreaders use the Chip Rate Agility module to trigger the generation of the M-ary symbols used in spreading. The chip rates result from sampling a uniform distribution and rounding to the nearest multiple of the data rate. The Chip Rate Agility module uses the Agility module to trigger generation of new blocks. Block lengths vary pseudorandomly, and are rounded to the nearest multiple of the data symbol duration.

The user specifies the minimum and maximum block lengths; the average chip rate as a multiple of the data rate; the maximum percentage one sided chip rate fluctuation; and whether the block lengths, block boundary pulses, instantaneous chip rate, and chip boundary pulses are stored. If the input signal has constant unit magnitude, the output power is 1.

Delays the output signal by the input delay value for automatic synchronization. Outputs the spreading sequence as a global output connector called 'code'.

LIBRARY / FUNCTION

prlib/communication

COMMUNICATOR'S ADAPTIVE THRESHOLD EXCISION SYSTEM

DESCRIPTION

Performs a spectral analysis of the input and removes the components with squared magnitude greater than an exceedance factor times a mean square magnitude. The mean square magnitude is of all the bins except a number of strongest bins. The user specifies the size of the FFT's, the number of strongest bins to be excluded from the calculation of mean square magnitude, the exceedance factor, and the type of window used in the forward FFT. The inverse FFT always uses a rectangular window. This algorithm recomputes the threshold for each successive block of data and so adapts to changing background levels.

The user has the option of storing the spectra before and after excision. The user specifies a filename stem, and the Vulnerability Metric appends ".in" and ".out" to stem to form the names of the files storing the spectra before and after excision respectively. The Vulnerability Metric writes all signal files to the directory /spwdata/vmsigs.

Taking the FFT delays the signal by a number of iterations equal to the FFT size, so the signal value presented at the DELAY OUT port is equal to the value at the DELAY IN port plus the FFT size.

COMMUNICATOR'S FIXED EXCISION SYSTEM

DESCRIPTION

Performs a spectral analysis of the input and removes the strongest components. The user specifies the size of the FFT's, the number of strongest bins to be excised, and the type of window used in the forward FFT. The inverse FFT always used a rectangular window. The frequency resolution, or bin size, is the sampling frequency divided by the FFT size. If the FFT size is N, simulation samples numbered 0 through N-2 are in the first block, N-1 through N-2 in the second block, and so on.

The user has the option of storing the spectra before and after excision. The user specifies a filename stem, and the Vulnerability Metric appends ".in" and ".out" to stem to form the names of the files storing the spectra before and after excision respectively. The Vulnerability Metric writes all signal files to the directory /spwdata/vmsigs.

Taking the FFT delays the signal by a number of iterations equal to the FFT size, so the signal value presented at the DELAY OUT port is equal to the value at the DELAY IN port plus the FFT size.

LIBRARY / FUNCTION

prlib/freq_excision

COMMUNICATOR'S WHITENING EXCISION SYSTEM

DESCRIPTION

Performs a spectral analysis of the input and divides each spectral component by its magnitude resulting in flat output spectrum.. The user specifies the size of the FFT's, and the type of window used in the forward FFT. The inverse FFT always uses a rectangular window. The spectral resolution, or bin size, is the sampling frequency divided by the FFT size. If the input spectrum in any bin is smaller than the machine's arithmetic resolution, the magnitude is set to 1, and the phase is arbitrarily set to 0. If the FFT size is N, simulation samples numbered 0 through N-2 are in the first block, N-1 through N-2 in the second block, and so on.

The user has the option of storing the spectra before and after excision. The user specifies a filename stem, and the Vulnerability Metric appends ".in" and ".out" to stem to form the names of the files storing the spectra before and after excision respectively. The Vulnerability Metric writes all signal files to the directory /spwdata/vmsigs.

Taking the FFT delays the signal by a number of iterations equal to the FFT size, so the signal value presented at the DELAY OUT port is equal to the value at the DELAY IN port plus the FFT size.

CUSTOM INTERFERENCE

DESCRIPTION

Reads an interference configuration supplied by the user and adds the result to the signal. The user specifies the number of interferers, the configuration center, interferer powers, in dB above communication signal power, and the widths. The bandwidth is implemented by BPSK modulating each interference carrier frequency equal to the bandwidth. The user specifies the name of the file configuration, the default name begins custom.conf. The format of the file is a format created by the Random Interference Module, so that configuration randomly and saved may be reused directly by the Custom Interference Module.

The mathematical form of the interference is the same as that detailed for Random Interference.

MENU PATH

freq_zoom	Frequency zoom, power of 2

USAGE EXAMPLE

SSVM>Demonstrations>Search Chip Rate Detector

LIBRARY / FUNCTION

delib/delay_chip_fft

DELAY, STEPPING SEARCH, CHIP RATE DETECTOR

DESCRIPTION

Combines a delay chip rate detector with a two-dimensional search that scans receiver center frequency and chip rate. The chip rate cycles through a fixed number of values specified by the user, while the receiver center frequency keeps incrementing throughout the simulation, once after each cycle through the chip rate, so the number of center frequencies used depends on the number of collects simulated and the number of chip rates used. The user controls the order and passband edge attenuation of the receiver filter and specifies the name, **filename**, of the file to which the results are written.

After the simulation, the user obtains a Gnuplot screen plot by entering

```
DelSrch filename
```

in an operating system window. The plot also displays the name of the underlying data file. To obtain a hard copy in addition to the screen plot, the user enters

```
DelSrch -h filename
```

If the default printer has not been set during the session, the user may have to specify the printer to be used by entering, in the operating system window, **setenv PRINTER** followed by the printer name. Quitting the graphics window, or typing a keystroke in the operating system window causes the graphical output to disappear, and the Gnuplot session to close.

DelSrch is a Bourne shell script which selects and edits the file **DelSrch.hard.template** if the flag **-h** is present, and **DelSrch.soft.template** otherwise, and calls Gnuplot to execute the resulting Gnuplot script, **DelSrch.gnu**. The data file and the script files are in the directory **/spwdata/vmsign**, but **DelSrch** can be invoked from any directory without specifying a path.

ENVELOPE, STEPPING SEARCH CHIP RATE DETECTOR

DESCRIPTION

Combines a envelope chip rate detector with a two-dimensional search that scans receiver center frequency and chip rate. The chip rate cycles through a fixed number of values specified by the user, while the receiver center frequency keeps incrementing throughout the simulation, once after each cycle through the chip rate, so the number of center frequencies used depends on the number of collects simulated and the number of chip rates used. The user controls the order and passband edge attenuation of the receiver filter and specifies the name, **filename**, of the file to which the results are written.

After the simulation, the user obtains a Gnuplot screen plot by entering

```
EnvSrch filename
```

in an operating system window. The plot also displays the name of the underlying data file, To obtain a hard copy in addition to the screen plot, the user enters

```
EnvSrch -h filename
```

If the default printer has not been set during the session, the user may have to specify the printer to be used by entering, in the operating system window, **setenv PRINTER** followed by the printer name. Quitting the graphics window, or typing a keystroke in the operating system window causes the graphical output to disappear, and the Gnuplot session to close.

EnvSrch is a Bourne shell script which selects and edits the file **EnvSrch.hard.template** if the flag **-h** is present, and **EnvSrch.soft.template** otherwise, and calls Gnuplot to execute the resulting Gnuplot script, **EnvSrch.gnu**. The data file and the script files are in the directory **/spwdata/vmsign**, but **EnvSrch** can be invoked from any directory without specifying a path.

ENVELOPE SPECTRUM

DESCRIPTION

Lowpass filters the incoming complex signal; buffers the signal into blocks; subsamples the blocks; forms a spectrum by performing an FFT and magnitude squaring the output; averages the results over a number of blocks, and stores the logarithm of the results for subsequent plotting.

After the simulation, the user enters

Spectrum filename

in an operating system window, where **filename** is the data file name selected by the user in the spectrum module. The result is a Gnuplot screen plot showing spectral strength as a function of frequency. The plot also displays the name of the underlying data file. To obtain a hard copy in addition to the screen plot, the user enters

Spectrum -h filename

If the default printer has not been set during the session, the user may have to specify the printer to be used by entering, in the operating system window, **setenv PRINTER** followed by the printer name. Quitting the graphics window, or typing a keystroke in the operating system window causes the graphical output to disappear, and the Gnuplot session to close.

Spectrum is a Bourne shell script which selects and edits the file **Spectrum.hard.template** if the flag **-h** is present, and **Spectrum.soft.template** otherwise, and calls Gnuplot to execute the resulting Gnuplot script, **Spectrum.gnu**. The data file and the script files are in the directory **/spwdata/vmsign**, but **Spectrum** can be invoked from any directory without specifying a path.

EXCEEDANCE

DESCRIPTION

Treats the inputs as the outputs of the histogram module, that is as the underflow, binned, and overflow counts of a real signal, and computes the exceedance. The exceedance of each bin is the number of counts larger than that bin's lower boundary, that is the number of counts in that bin plus the number of counts in all higher bins. The overflow is treated as a bin so the first, or highest component in the output vector is equal to the OVER input. The UNDER input is passed to the output for subsequent processing.

MENU PATH

Interceptor> Metrics > Exceedance

Coded in C

ENVELOPE, FFT SEARCH CHIP RATE DETECTOR

DESCRIPTION

Implements an envelope chip rate detector with an FFT output stage to permit detection at multiple chip rates. In addition the output stage provides filtering, subsampling and block averaging. The user can therefore tailor the search to cover efficiently the range of chip rate uncertainty. The documentation of the Envelope Spectrum Detector provides detailed information on the filtering, subsampling and block averaging.

offset	Offset applied to scaled values from file
sfreq	Sampling frequency

LIBRARY / FUNCTION

utlib/file_stepper

FILTERING

DESCRIPTION

Filters the complex envelope input with a lowpass filter that may be offset from the signal center frequency. The user controls the filter offset and bandwidth. The filter is a Butterworth IIR filter with an adjustable order preset at 20 and an adjustable passband edge attenuation preset to 3dB. The filtering module may only be used in the two weak signal operational modes of the Vulnerability Metric.

Communicators adjust the signal power so the transmitted power is constant, independent of the filtering. Direct simulation of power compensation would require an additional simulation to measure the impact of filtering on power. To maintain computational efficiency, the Vulnerability Metric allows the filter module to reduce the transmitted power, but measures and stores the reduction factor on disk at the end of the simulation. In both of the weak signal modes, the vulnerability assessment at the end of the simulation reads the power reduction factor and rescales the signal strength. From the user's perspective, the vulnerability evaluation runs exactly as if transmitted power were maintained constant.

Coded in C

FREQUENCY AGILITY

DESCRIPTION

Shifts the incoming signal's frequency and phase by random offsets which remain constant over time intervals called hops, and vary pseudorandomly between hops. Hop length, generated by the AGILITY module, also vary pseudorandomly, and are rounded to the nearest multiple of the data symbol duration. Typically the difference between the minimum and maximum hop lengths exceeds the data symbol duration, so the FREQUENCY AGILITY module performs slow frequency hopping with fluctuation hop lengths.

The user specifies the minimum and maximum block lengths; the number of frequency offsets; the maximum one sided frequency deviation; and whether the block lengths and block boundary pulses are stored. If the input signal has constant unit magnitude, the output power is 1.

MENU PATH

ESTIMATED OUTPUT SNR

DESCRIPTION

Estimates the output signal to noise ratio

$$(S/N)_0 = \frac{|E\{z|H_1\} - E\{z|H_0\}|^2}{Var\{z|H_1\}}$$

The denominator is a variance, and the first output of the variance estimators is zero, so the module's first output sample should be ignored.

GAMMA NOISE

DESCRIPTION

Produces a discrete complex envelope model of continuous bandpass white noise whose magnitude is distributed as a Gamma random variable, and whose phase is uniformly distributed. The marginal distributions of the real and imaginary components are not expressible as elementary functions, but decay exponentially. The probability density of the magnitude is given by

$$xe^{-x}$$

The noise power in both the Gaussian and Gamma Noise modules is parametrized by the communicator's input signal to noise ratio, which is computed for the case where only one noise module is present. Using more than one noise module at a time requires manually determining the input signal to noise ratio.

MENU PATH

Coded in C

HOLD SWITCH

DESCRIPTION

If the selection index parameter is zero, sets all outputs to TRUE. Otherwise sets all outputs to TRUE except one, which is identified by a selection index parameter. The module sets the selected port to FALSE. Another parameter specifies the number of options, that is the number of outputs available for the selection, plus one for the case where none is selected. The module sets the value of the both parameters, and terminates with an error message if either is out of range. Setting the parent module parameter permits the error message to give the containing module of the instance that has an error.

JITTER

DESCRIPTION

Produces trigger pulses at randomly occurring time steps. The random timing of the zeros is constrained: referring to the interval between successive zeros as a chip, there are always an integer number of chips in a data symbol, and the chip rate only changes at data symbol boundaries. The instantaneous chip rate is generated randomly by truncating a continuous uniform random variable to the nearest integer multiple of the data rate. The user specifies the mean and maximum deviation of the continuous random variable, with the mean parametrized as a multiple of the data rate, and the size of the chip rate fluctuations parametrized as a percentage of the average rate. The user also controls the interval between chip rate changes, parametrized as a multiple of the data symbol length, and the user may write to disk the instantaneous chip rate and the module output.

The terms "jitter" and "dither" are synonymous.

MENU PATH

Spread Spectrum > Jitter

INPUT PORT

None

OUTPUT PORT

OUT Real

PARAMETERS

nchav	Average number of chips per symbol
nsybj	Number of symbols between chip rate changes
hw	Maximum allowed deviation of chip rate from average chip rate
write_jitter	1 to write instantaneous chip rate and chip release impulses to files, 0 otherwise
fda	Data rate
sfreq	Simulation sampling frequency

LIBRARY / FUNCTION

walib/jitter

JITTERED 8ary DS SPREADER

DESCRIPTION

Multiplies the complex input by a 8-ary complex pseudonoise sequence with a fluctuation chip rate. The user specifies the average chip rate as a multiple of the data rate, the size of the chip rate fluctuations as a percentage, and the interval between chip rate changes as a multiple of the data symbol length. Optionally stores the instantaneous chip rate and the sequence of impulses that trigger each chip. If the input signal has constant unit magnitude, the output power is 1.

LOWPASS CYCLIC SPECTRUM

DESCRIPTION

Computes the lowpass component of the cyclic spectrum of a complex signal SDE. The lowpass cyclic spectrum is computed at a user-specified cyclic frequency and for spectral frequencies between $f_0 - f_{sa}/2$ and $f_0 + f_{sa}/2$ where f_{sa} is the sampling frequency and f_0 is the signal center frequency.

The estimation of cyclic spectra combines the analysis of Appendix E with functions in COMDISCO's Signal Display Editor, SDE. The final implementation in SDE is a macro which has performed successfully in test, although errors in COMDISCO's documentation hinder an analytic proof of correctness.

MAKE ROC

DESCRIPTION

Treats each pair of inputs as the outputs of the exceedance module, that is as a vector of exceedances and an underflow, and uses each pair of inputs to estimate the probability distribution function of the corresponding real signal. There are two pairs of inputs, one for the signal present and the other for the signal absent simulation, and the module combines the two probability distribution estimates to form probability of false alarm, probability of detection, pairs. The user specifies a name, **filename**, in the parameter table, and the module stores probability pairs in that file, in the directory **/pspdata/vmsigs**. To control statistical significance, the user specifies a minimum exceedance count number for the signal absent input, and the module terminates the tail of the ROC at the bin where the number of counts goes below the minimum. In addition, the module writes the complete set of probability pairs to a second file with a name formed by adding the extension **.all** to **filename**.

MENU PATH

MMSE WHITENING FILTER

DESCRIPTION

Implements an adaptive whitening matched filter, which acts to excise interference by estimating the signal plus noise power spectral density and inverting it in the frequency domain. Rather than actually excising interferers, this module deemphasizes the frequency bands in which they fall. Blocking effects are mitigated by overlapping successive blocks to which a complementary taper has been applied.

MENU PATH

Communicator > Preprocessor > MMSE

INPUT PORTS

IN Complex

OUTPUT PORT

OUT Complex

PARAMETERS

blocksize	Length of FFT
average_type	Periodogram averaging type, either 'sliding_block' or 'decaying'
averaging_block	Length of sliding window of 'sliding_block' averaging type
danielle_param	Width of frequency domain smoothing window
alpha	Decay parameter of 'decaying' average type
window_type	Tapering window applied to lapped reconstruction blocks, either 'hanning' or 'bartlett' are recommended
sfreq	Sampling frequency

LIBRARY / FUNCTION

prlib/lapped_adapt

MODE 1

DESCRIPTION

Estimates the full output SNR, defined in Appendix F as

$$(S/N)_0 = \frac{|E\{z|H_1\} - E\{z|H_0\}|^2}{Var\{z|H_1\}}$$

and writes the final estimate to a file. The user specifies the filename as a parameter.

MENU PATH

Interceptor > Metrics > Mode 1

INPUT PORTS

H1 Complex

H0 Complex

HOLD Real

OUTPUT PORTS

None

PARAMETERS

filename Filename to store results

LIBRARY / FUNCTION

vulib/mode_1

MODE 2

DESCRIPTION

Estimates the full output SNR, per collected bit, and writes the result to a file. The full output SNR is defined as

$$(S/N)_0 = \frac{|E\{z|H_1\} - E\{z|H_0\}|^2}{Var\{z|H_1\}}$$

and the number of collected symbols is the product of the data rate and the collect time.

The Vulnerability Metric extrapolates the result to a range of collect times. After the simulation, a window appears prompting the user to obtain a Gnuplot screen plot by entering

Plot2 filename

in an operating system window, where **filename** is the data file name selected by the user. The plot also displays the name of the underlying data file. To obtain a hard copy in addition to the screen plot, the user enters

Plot2 -h filename

If the default printer has not been set during the session, the user may have to specify the printer to be used by entering, in the operating system window, **setenv PRINTER** followed by the printer name. Quitting the graphics window, or typing a keystroke in the operating system window causes the graphical output to disappear, and the Gnuplot session to close.

Plot2 is a Bourne shell script which selects and edits the file **Plot2.hard.template** if the flag **-h** is present, and **Plot2.soft.template** otherwise, and calls Gnuplot to execute the resulting Gnuplot script, **Plot2.gnu**. The data file and the script files are in the directory **/spwdata/vmsign**, but **Plot2** can be invoked from any directory without specifying a path.

LIBRARY / FUNCTION

vulib>mode_3

MODE 4

DESCRIPTION

Estimates the output signal noise ratio defined as

$$\frac{|E\{z | Sig\}|^2}{Var\{z | H_0\}}$$

and stores the result in a file as a coefficient which permits extrapolation of the result to a range of collect times and a range of interceptor's input signal power. The extrapolation to a range of signal powers is accurate only for low signal powers, and the module ensures that results are presented over a range where they are accurate.

The module uses the results of analytic calculations to determine the denominator, thereby shortening the computation in two ways. First the signal absent case does not need to be simulated, and second, estimates of the mean converge faster than estimates of the variance, so the simulation does not have to be as long to achieve a given accuracy.

The extrapolation to a range of signal powers is accurate only for low signal powers, and the module ensures that results are presented over a range where they are accurate.

The user also has the option of storing intermediate statistics on disk. The user selects the filenames.

After the simulation, a window appears prompting the user to obtain a Gnuplot screen plot by entering

Plot4 filename

in an operating system window, where **filename** is the data file name selected by the user. The plot also displays the name of the underlying data file. To obtain a hard copy in addition to the screen plot, the user enters

Plot4 -h filename

If the default printer has not been set during the session, the user may have to specify the printer to be used by entering, in the operating system window, **setenv PRINTER** followed by the printer name. Quitting the graphics window, or typing a keystroke in the operating system window causes the graphical output to disappear, and the Gnuplot session to close. **Plot3** is a Bourne shell script which selects and edits the file **Plot3.hard.template** if the flag **-h** is present, and **Plot3.soft.template** otherwise, and calls Gnuplot to execute the

RANDOM INTERFERENCE

DESCRIPTION

Randomly generates an interference configuration and adds the resulting interference to the signal. The user specifies the number of interferers, and the maxima and minima of the interferer width and carrier frequency distributions, and the mean and standard deviation of the interferer power distribution. A configuration of interferers is then randomly generated from the specified distributions and the resulting interference background is added to the signal. The frequency and bandwidth of each interferer are generated from uniform distributions with upper and lower limits specified by the user. The power of the interferers is generated from a power law probability density, with the mean power and the variance specified by the user. The bandwidth is implemented by BPSK modulating each interference carrier at a modulation frequency equal to the bandwidth. The interference configuration is stored in a file. The user may specify the filename, which defaults to rand.conf..

The interference is given by

$$\sum_{i=1}^N \sqrt{2P_i} e^{j2\pi(f_i-f_0)n/f_{sa}} b_i \left\{ \text{Floor} \left(\frac{nW_i}{f_{sa}} \right) \right\}$$

where n is the sample number, N is the number of interferers, f_{sa} is the simulation sampling frequency, f_0 is the center frequency of the communication signal, and P_i, f_i, W_i and b_i are respectively the power, carrier frequency, one-sided bandwidth and a pseudonoise binary data sequence of the i th interferer. The data sequence has values ± 1 .

RECEIVER

DESCRIPTION

Simulates a real receiver or tuner, which filters the incoming real signal to reduce noise contamination of the detection processing, and converts the result to a complex envelope form centered on the center frequency of the input passband. Since the entire simulation uses complex envelope representation, the simulation model of the real bandpass filtering is complex lowpass filtering. The Receiver module, by incorporating the Center Frequency between the receiver center frequency and the signal center frequency. The filter model used is a Butterworth IIR filter with an adjustable order set at 20.

RICIAN ROC

DESCRIPTION

Samples the output of a detector at intervals equal to the detector's collect time; forms estimates of the mean and variance of the incoming signal; treats the magnitude of the mean as the amplitude of a tone, and the variance as the variance of Gaussian noise; and computes the receiver operating characteristic (ROC) of the detection of the tone in the Gaussian noise using an envelope centered on the tone frequency. The resulting ROC is an approximation to the true ROC because the envelope used may not be exactly centered on the feature frequency, and the detector output noise will in general not be exactly Gaussian. By setting the flag in the parameter table, the user may also store the progressive estimates of the variance and the amplitude of the mean for subsequent viewing in SDE. The user specifies the name, **filename**, of the file to which the results are written.

After the simulation, the user enters

Rician filename

in an operating system window, where **filename** is the data file name selected by the user in the spectrum module. The result is a Gnuplot screen plot showing spectral strength as a function of frequency. The plot also displays the name of the underlying data file. To obtain a hard copy in addition to the screen plot, the user enters

Rician -h filename

If the default printer has not been set during the session, the user may have to specify the printer to be used by entering, in the operating system window, **setenv PRINTER** followed by the printer name. Quitting the graphics window, or typing a keystroke in the operating system window causes the graphical output to disappear, and the Gnuplot session to close.

The module writes the mean and variance to files called **rician_roc_mean.dat** and **rician_roc_var.dat** respectively. When the simulation is over, the custom coded module STORE RICIAN ROC RESULTS reads both files and writes the variance and the amplitude of the mean to a single file with name, **filename**, specified by the user in the parameter table of RICIAN ROC. **Rician** is a Bourne shell script which selects and edits the file **Rician .hard.template** if the flag **-h** is present, and **Rician .soft.template** otherwise, and calls Gnuplot to execute the resulting Gnuplot script, **Rician .gnu**. The data file and the script files are in the directory **/spwdata/vmsign**, but **Rician** can be invoked from any directory

RICIAN ROC, continued

A second Bourne shell script also permits the user to integrate communication performance results with the Rician ROC. After the simulation, the user obtains a screen plot by entering

```
Rician filename1 filename2
```

where the additional filename, **filename2**, is the name specified by the user in the BIT ERROR RATE module to store the bit error rate estimate. The functionality of **BerRic** is similar to the functionality of **Rician**, with the addition that the bit error rate estimates and the name of the file used to store it are both shown in the title of the plot. As with **Rician**, using the flag -h produces a hard copy as well as the screen plot.

LIBRARY / FUNCTION

vulib/roc_rician

ROC

DESCRIPTION

Forms histograms of the magnitudes of samples of two input, one for signal present and the other for signal absent, and uses the results to estimate the receiver operating characteristic (ROC). The sampling interval is equal to the collect time used in the detector module. The user specifies the lowest and highest values of the detection threshold to be considered, the number of bins into which the intervening range is divided, and the name, **filename**, of the file to which the results are written. .

After the simulation, the user enters

ROC filename

in an operating system window, where **filename** is the data file name selected by the user in the spectrum module. The result is a Gnuplot screen plot showing spectral strength as a function of frequency. The plot also displays the name of the underlying data file. To obtain a hard copy in addition to the screen plot, the user enters

ROC -h filename

If the default printer has not been set during the session, the user may have to specify the printer to be used by entering, in the operating system window, **setenv PRINTER** followed by the printer name. Quitting the graphics window, or typing a keystroke in the operating system window causes the graphical output to disappear, and the Gnuplot session to close.

ROC is a Bourne shell script which selects and edits the file **ROC.hard.template** if the flag **-h** is present, and **ROC.soft.template** otherwise, and calls Gnuplot to execute the resulting Gnuplot script, **ROC.gnu**. SCANNER

DESCRIPTION

Cyclically scans a set of frequency channels and stops when the average power detected exceeds a threshold. The scanner frequency then remains fixed until the average power drops below the threshold, when the scanning continues. The channel center frequencies are either uniformly spaced in a band specified by the user, or listed in a file supplied by the user.

The file must exist in /caedata/data. The power average is a moving average over an interval equal to the channel dwell time. The threshold is a user-specified multiplier times the average power obtained from a reference signal that is typically known to contain no signal.

The user has the options to store intermediate signals inside the scanning radiometer and inside the reference radiometer. The Vulnerability Metric stores the signals in /spwdata/vmsigs, with filenames based on the stem supplied by the user.

LIBRARY / FUNCTION

utlib/sine_wave

SPECTRA

DESCRIPTION

Filters and subsamples the input, then forms the magnitude squared of the Fourier Transform of the subsampled signal, and finally performs a sliding block average of the resulting spectrum. The process repeats and the averaged spectra are stored in ASCII format in a data file with name specified by the user as a parameter. The user also specifies the value of a spectrum width parameter and the actual spectrum width is rounded up to a submultiple of the sampling frequency.

Sampling Frequency

Actual Spectrum Width = -----
Floor (Sampling Frequency/ Spectrum Width Parameter)

The bandwidth of the input filter is set equal to the Actual Spectrum Width to eliminate aliasing, resulting in spectrum edges contaminated by the filter band edges. As an aid to the user, updating an additional parameter shows the duration of signal input required to form each averaged spectrum.

After the simulation, the user enters

Waterfall filename

in an operating system window, where **filename** is the data file name selected by the user in the spectrum module. The result is a Gnuplot screen plot showing spectral strength as a function of frequency. The plot also displays the name of the underlying data file, To obtain a hard copy in addition to the screen plot, the user enters

Waterfall -h filename

If the default printer has not been set during the session, the user may have to specify the printer to be used by entering, in the operating system window, **setenv PRINTER** followed by the printer name. Quitting the graphics window, or typing a keystroke in the operating system window causes the graphical output to disappear, and the Gnuplot session to close.

Waterfall is a Bourne shell script which selects and edits the file **Waterfall.hard.template** if the flag **-h** is present, and **Waterfall.soft.template** otherwise, and calls Gnuplot to execute the resulting Gnuplot script, **Waterfall.gnu**. The data file and the script files are in the directory **/spwdata/vmsign**, but **Waterfall** can be invoked from any directory without specifying a path.

SPECTRUM

DESCRIPTION

Starts at a time specified by the user, filters and subsamples the input, then forms the magnitude squared of the Fourier Transform of the subsampled signal, and finally performs a sliding block average of the resulting spectrum. The averaged spectra are stored in ASCII format in a data file with name specified by the user as a parameter. The user also specifies the value of a spectrum width parameter and the actual spectrum width is rounded up to a submultiple of the sampling frequency.

$$\text{Actual Spectrum Width} = \frac{\text{Sampling Frequency}}{\text{Floor (Sampling Frequency/ Spectrum Width Parameter)}}$$

The bandwidth of the input filter is set equal to the Actual Spectrum Width to eliminate aliasing, resulting in spectrum edges contaminated by the filter band edges. As an aid to the user, updating an additional parameter shows the duration of signal input required to form each averaged spectrum.

After the simulation, the user enters

Spectrum filename

in an operating system window, where **filename** is the data file name selected by the user in the spectrum module. The result is a Gnuplot screen plot showing spectral strength as a function of frequency. The plot also displays the name of the underlying data file. To obtain a hard copy in addition to the screen plot, the user enters

Spectrum -h filename

If the default printer has not been set during the session, the user may have to specify the printer to be used by entering, in the operating system window, **setenv PRINTER** followed by the printer name. Quitting the graphics window, or typing a keystroke in the operating system window causes the graphical output to disappear, and the Gnuplot session to close.

Spectrum is a Bourne shell script which selects and edits the file **Spectrum.hard.template** if the flag **-h** is present, and **Spectrum.soft.template** otherwise, and calls Gnuplot to execute the resulting Gnuplot script, **Spectrum.gnu**. SQUARE WAVE

DESCRIPTION

Outputs a square wave z_n with frequency exactly as given by the frequency input f_n

$$z_n = \text{SquareWave}(2\pi f_n n / f_{sa})$$

where f_{sa} is the simulation sampling frequency. In contrast to the SPW implementation of function generators, the frequency is not rounded to the inverse of an integer number of simulation sampling intervals.

LIBRARY / FUNCTION

utlib/square_wave

STEPPER

DESCRIPTION

Produces a stepped output which cycles through a set of values specified by the user. In the auto mode, the values are regularly spaced and specified by the starting value, the increment, and the number of values. Alternatively the user may store arbitrary values in a file in the directory **/caedata/data/**, and specify a scaling factor and a offset to be applied to the values in the file. The user controls the name of the file, and the dwell time, which is the time interval between changes in the output.

A file with the chosen name must be present in **/caedata/data/** , even if it is not used because the user chooses the auto mode.

STORE SPECTRA

DESCRIPTION

Stores the input vectors and a vector of frequencies in columns in an ASCII file `/spwdata/vmsigs/`. At each iteration the elements of the input vector at SPECTRA are reordered to place the zero frequency component in the center to the first column in the file. Parameters define the width of the spectrum and frequencies, and the module computes a vector of frequencies and appends the column in the file. The user may zoom in on the input spectrum by only plot the spectrum, centered at zero frequency, with the ratio of the total spectrum, size being a power of two specified by the user. Coded in C.

MENU PATH

LIBRARY / FUNCTION

delib/store_spectra

STORE THREE DIMENSIONAL DATA

DESCRIPTION

Treats each component of the input vector as the value of a function of two variables. The value of the first variable increments from one iteration to the next, while the value of the second variable increments from one component of the input vector to the next. The module stores the data in a file as triplets, with one triplet per line, and each triplet consisting of the values of the first variable, the second variable and the vector component. Tabs separate numbers on a line. Coded in C.

SWITCHED RADIOMETER SYSTEM

DESCRIPTION

Uses a communication signal input and a background input to form, a signal present input to one detector and a signal absent input to another detector. The detectors are each radiometer detectors, and an additional input port permits the user to supply the switching frequency which both adds to the incoming signal and serves as the switched reference source processing the signal present case is the H_1 output and the result of processing the signal absent case is the H_0 output. Stores detector parameter values in files.

MENU PATH

TAPPED DELAY LINE

DESCRIPTION

Outputs the weighted sum of the input signal and $N - 1$ delayed samples of the input signal. The number of taps, N , equals the integer truncation of the product of the spread T_{sp} and the simulation sampling frequency f_{sa} . The weights are read from an input file built by the user. The number of taps must be less than or equal to 512. The output signal $y(n)$ is given by

$$y(n) = \sum_{k=0}^{N-1} c_k x(n-k)$$

where $x(n)$ is the input signal, n is the sample number, c_k are the weights input by the user, and

$$N = \text{Floor}(T_{sp} f_{sa})$$

MENU PATH

MISSION
OF
ROME LABORATORY

Mission. The mission of Rome Laboratory is to advance the science and technologies of command, control, communications and intelligence and to transition them into systems to meet customer needs. To achieve this, Rome Lab:

- a. Conducts vigorous research, development and test programs in all applicable technologies;
- b. Transitions technology to current and future systems to improve operational capability, readiness, and supportability;
- c. Provides a full range of technical support to Air Force Materiel Command product centers and other Air Force organizations;
- d. Promotes transfer of technology to the private sector;
- e. Maintains leading edge technological expertise in the areas of surveillance, communications, command and control, intelligence, reliability science, electro-magnetic technology, photonics, signal processing, and computational science.

The thrust areas of technical competence include: Surveillance, Communications, Command and Control, Intelligence, Signal Processing, Computer Science and Technology, Electromagnetic Technology, Photonics and Reliability Sciences.
